ABSTRACT: Objectives: The current study aimed to perform a meta-analysis to comprehensively investigate effect of physical activity on cognitive function in people with Mild Cognitive Impairment. The findings of this study can offer an important basis for identifying the significance of physical activity as an important factor in designing and implementing strategies to enhance cognitive function in mild cognitive impairment. Methods: 21 articles were selected through academic databases (EBSCOhost, PubMed, ScienceDirect, Web of Science), and 20 Montreal Cognitive Assessment (MoCA) data and 15 Mini-Mental State Examination (MMSE) data were obtained. The study was conducted using the meta-analysis. To test the validity of each article included in this study, a funnel plot and Egger's regression analysis were carried out to check for publication bias. Results: The 95% confidence interval (CI) for the effect size was interpreted as a small effect size if the effect size was between 0.2 and 0.5, a moderate effect size if the effect size was between 0.5 and 0.8, and large if the effect size was greater than 0.8. First, the meta-analysis of MoCA data showed a large effect size of 0.96; second, the meta-analysis of MMSE data indicated a large effect size of 0.93; and third, the meta-analysis of MoCA and MMSE data together indicated a moderate effect size of 0.68. Conclusion: The current study demonstrates the significant effect of physical activity on cognitive function and provides a basis for developing programs to improve cognitive function. People diagnosed with mild cognitive impairment generally experience minimal disruption in daily living activities. However, as the severity of the condition progresses, significant challenges emerge, impacting the individual's ability to carry out daily tasks. Research has demonstrated that physical activity can enhance cognitive function in individuals with MCI. Consequently, it is recommended that these individuals be motivated to participate in physical activity to optimize their cognitive function and enhance their overall quality of life.

KEYWORDS: Physical activity; mild cognitive impairment (MCI); montreal cognitive assessment (MoCA); minimental state examination (MMSE); meta-analysis

1 Introduction

Mild Cognitive Impairment (MCI) is a state distinguished by cognitive decline and other types of dementia [1]. MCI is a shifting condition from normal aging to dementia that does not substantially affect daily life [2]. Therefore, people with MCI are often unaware of it. However, 10%–15% of people over the age of 65 have cognitive disorders, and more than half of them are at serious risk of progressing to dementia within five years [3]. Cognitive impairment not only highly impacts the life satisfaction of life of older adults, but also places a severe economic burden on healthcare [4,5]. Therefore, there is a need to detect, prevent, and treat them before they lead to significant cognitive decline, such as dementia.

The MCI is generally diagnosed by the standardized Montreal Cognitive Assessment (MoCA) and Mini-Mental State Examination (MMSE) [6,7]. Both instruments can assess cognitive function in a relatively short time and without special tools or equipment, with 30 points. Higher points indicate higher cognitive function. However, the cutoff points for MCI are slightly different. Generally, a point of \geq 26 for MoCA and \geq 24 for MMSE is considered normal. However, since both tools are simple screening tests, it is important to have a detailed diagnosis and evaluation by a specialist to make a final diagnosis. The MoCA assesses visuospatial/executive, vocabulary, attention, sentence, abstract, recall, and passing, while the MMSE assesses time, place, memory registration, attention and computation, memory recall, language, and spatial organization. The MoCA was developed as a method for quick screening of MCI [8]. Therefore, it has been proven to have high specificity and sensitivity in confirming MCI [9]. In contrast, the MMSE is relatively not sensitive enough to confirm MCI, but it is more specific and appropriate for diagnosing dementia [10].

Physical activity on a regular basis is a significant strategy to improve cognitive performance [11,12]. Many studies have indicated that people with MCI can maintain or return to normal cognitive levels with proper strategies [13,14]. Some studies in the field of neuroimaging have argued that physical activity is significantly effective in reducing cognitive function in older adults with and without cognitive impairment [15,16]. Moreover, some longitudinal studies for healthy adults have also revealed that engaging in physical activity strategies has effects on improving cognitive function and enhanced brain volume in the brain [17–19]. However, other studies have reported little gap in cognitive function between physical activity strategy and health education programs in longitudinal studies [20], and very limited evidence that specific physical activity in elderly people with MCI is unclear [22]. To integrate the results of these conflicting individual studies, we conducted a meta-analysis with a systematic literature review.

The current study aims to verify the effect of physical activity by providing comprehensive and objective evidence of the disseminative to which physical activity has an effect on cognitive function in MCI through meta-analysis. The findings of this study can offer a significant basis for identifying the importance of physical activity as an important factor in designing and implementing strategies to improve cognitive function in MCI.

2 Methods

2.1 Data Search

The current study followed the PRISMA 2020 guideline [23]. We carried out a literature search for research publications between January 2014 and August 2024. EBSCOhost, PubMed, ScienceDirect, and Web of Science were used for the literature search. In each academic database, we searched for ("Montreal Cognitive Assessment (MCA)" OR "Mini-Mental State Examination (MMSE)") AND ("physical activity" OR "exercise" OR "walking" OR "swimming" OR "cycling").

2.2 Selection Criteria

The inclusion criteria for the literature were adopted and searched referring to PICOS [24]. First, participants were required to have mild cognitive impairment. Second, the treatment and program (strategy) of the experimental group was physical activity. Third, the control group did not apply physical activity as a treatment method and program. Fourth, the results were MoCA and MMSE. Fifth, the study with a randomized controlled trial (RCT) was adopted. Sixth, if a single article included more than one physical activity group, we included all of them. Seventh, we included all studies that examined both MoCA and MMSE in a single study. The characteristics of the studies selected according to PICOS are shown in Table 1.

Table 1 (continued)

2.3 Selection Process

In the initial stage of the data selection, 2078 articles from EBSCOhost, 1353 from PubMed, 317 from ScienceDirect, and 1245 from Web of Science were retrieved. Of these, we excluded 3371 duplicates, and 1581 were eliminated by reviewing the titles and abstracts; finally, the remaining 21 articles were chosen and used for the current study. The PRISMA flow chart of the literature selection process is shown in Fig. 1 [43].

2.4 Coding

Authors (year of publication), age of participants, exercise program (intervention), duration of treatment, and measurement were coded as shown in Table 1. If a study included more than one physical activity group, we coded them in separate rows. If a study assessed both MoCA and MMSE, we entered both instruments in the instrument field. The data was coded by two PhDs in sport psychology, and a professor of sports and exercise psychology was consulted in the event of disparities during the coding process.

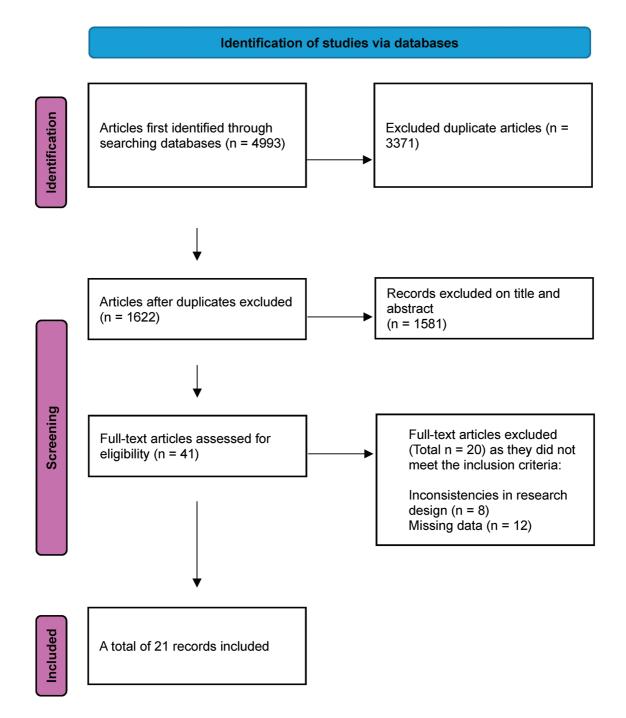

Figure 1: Flowchart outlining article selection process

2.5 Statistical Analysis

The R program (ver. 4.3.3) was applied for the meta-analysis and the effect size was determined based on Cohen's recommendation [44]. The I² value was applied to test the heterogeneity of the selected articles and Schmitt et al. indicated the level of heterogeneity ($I^2 = 25\%-50\%$: low heterogeneity, 50%–75%: moderate heterogeneity, 75% or more: high heterogeneity) [45]. Additionally, a random-effects model was chosen if high heterogeneity appeared among the included studies, and a fixed-effect model was chosen for low heterogeneity [45]. To test the validity of each article included in this study, a funnel plot and Egger's regression analysis were carried out to confirm publication bias [46].

3 Results

3.1 General Characteristics of the Selected Literature

21 articles were selected for analysis in this study. However, six studies included two physical activity groups in one study and eight studies examined both MoCA and MMSE. Therefore, a total of 35 studies were analyzed. The participants were aged 50 years or older with MCI. Participants participated in a physical activity program (intervention) of 6 to 36 weeks.

3.2 Publication Bias

We performed funnel plots and Egger's regression tests to check publication bias. The funnel plot for the MoCA data is presented in Fig. 2a, and the regression analysis reveals that there is no publication bias (=2.2829; t = 1.99, df = 18, p = 0.0616). The funnel plot for the MMSE data is indicated in Fig. 2b, and the regression reveals that there is no publication bias (=2.0506; t = 1.75, df = 13, p = 0.1044). In contrast, when MoCA data and MMSE data were regressed together (bias = 2.0513; t = 2.71, df = 33, p = 0.0106) indicated publication bias, so we adjusted the publication bias (=0.2837; t = 0.32, df = 42, p = 0.7537) by adding 9 articles using a trim-and-fill algorithm. The adjusted funnel plot is presented in Fig. 2c.

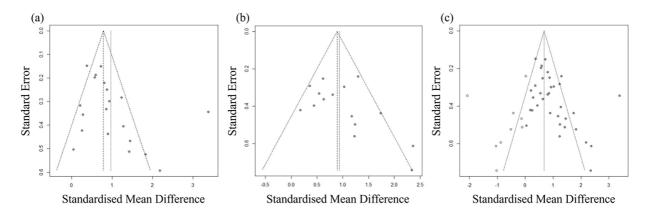

Figure 2: Funnel plots. (a) Funnel plot of MoCA; (b) Funnel plot of MMSE; (c) Adjusted funnel plot of MoCA and MMSE

3.3 Meta-Analysis

The findings of the MoCA data analysis are shown in Fig. 3. The heterogeneity among the studies was considered statistically significant ($I^2 = 79.7\%$, p < 0.001) by analyzing with a random-effects model. The effect size was 0.9648 (95% CI = 0.6344, 1.2952), which revealed a large effect size and a significant difference (z = 5.72, p < 0.001). The findings of the MMSE data analysis are also shown in Fig. 3. Given the significant heterogeneity among the studies ($I^2 = 49.8\%$, p = 0.0148), a random effects model was applied. From this analysis, the effect size was 0.9317 (95% CI = 0.6700, 1.1933), which revealed a large effect size, and there was a statistically significant difference (z = 6.98, p < 0.001). In addition, the results of the MOCA and MMSE data analysis together are demonstrate in Fig. 3. As the heterogeneity between the included studies was significant ($I^2 = 72.2\%$, p < 0.001), a random effects model was applied. The effect size was 0.9605 (95% CI = 0.7383, 1.1828), which is a large effect size, and there was a statistically significant difference (z = 8.47, p < 0.001).

263

However, regressing the MoCA and MMSE data together showed publication bias, so publication bias was adjusted using a trim-and-fill algorithm. Fig. 4 shows the findings of the meta-analysis after adjusting bias. The effect size was 0.6776 (95% CI = 0.4029, 0.9523), demonstrating a moderate effect size, and there was a statistically significant difference (z = 4.84, p < 0.001).

Figure 4: Adjusted forest plot of combined MoCA and MMSE [1,2,10,25-42]

4 Discussion

A meta-analysis was performed to comprehensively analyze and confirm the effect of physical activity on MCI. As a result, the effect size of physical activity on the MoCA score of MCI was 0.96 and the MMSE score was 0.93, which both values were large. Moreover, when the MoCA and MMSE scores were analyzed together, the effect size before adjusting for publication bias was 0.96, while after adjusting the effect size was 0.68, which was a moderate effect size. The findings can be explained that physical activity has a significant effect on MCI. The publication bias is likely because the MoCA and MMSE tests have the same total score, but different assessment criteria and sensitiveness and specification of the cognitive function assessment tools.

The current findings indicated that physical activity significantly improves cognitive function demonstrating that cognitive function scores increased in all included studies. However, none of the studies showed statistical differences between groups. When analyzed by type of physical activity, the intervention effects of aerobic exercise [33], dance [25,37], and training with elastic bands did not show statistical differences in MoCA scores when trained at low speeds, although some studies showed statistical differences between walking and multicomponent or combined exercise [26,40,41], while others have not [10,31]. However, statistical differences were found for resistance exercise [29], Tai Chi [26,41], Baduanjin [38,39], and traditional Thai exercise [32]. A meta-analysis of studies examining the effects of exercise in individuals with MCI revealed a modest effect, with a 42% effect size for clinical outcomes and an 8% effect size for cognitive outcomes, which was statistically significant [21]. It can be inferred that different types of physical activity produce different effects on cognitive function.

Furthermore, when analyzed according to the duration of the physical activity program, walking did not show differences after 6 months of participation [42]. However, a longer intervention of 36 weeks showed a statistical difference even for relatively low-intensity exercises such as walking [26], and for multicomponent exercises, some studies found no statistical difference after 12 weeks of intervention [31], while others found a statistical difference [1]. When looking at resistance exercise programs, the studies that showed a statistical difference used three 80 min exercises per week, while the studies that did not show a statistical difference used two 90 min exercises per week. This suggests that the intensity of exercise may also be a crucial factor in cognitive improvement. In the case of resistance training and ground kayaking, there was a statistical difference between the two exercise programs, even after a short six-week period of participation. A meta-analysis of cognitive function studies in mildly cognitively impaired individuals also found significant improvements in short-term memory, attention, visual-spatial/executive function, and global cognitive function [47]. Taken together, these findings imply that the type of exercise, intensity, and duration of the intervention can affect cognitive function.

Previous research has reported that complex physical activity combined with strenuous mental activities can help enhance physical and cognitive function [48]. In recent, mind-body exercises such as Tai Chi [26,41], Baduanjin [38,39], and Ruesi Dadton have been studied for their positive effect on cognitive function [32]. The findings indicated that cognitive function improved with statistically significant differences, and that mind-body exercises were more effective in promoting cognitive function compared to walking [26,42]. Mind-body exercises include various activities such as skeletal muscle relaxation and stretching, as well as body coordination and regular breathing movements [49]. In addition, meditative states are also involved in mind-body exercises to regulate attention and consciousness [50]. In particular, mind-body exercises are comparatively mild intensity and slow pace compared to aerobic or resistance exercises, making them suitable for older people with MCI.

In recent, it has become plausible to non-invasively assess cortical brain activity using near-infrared light in human subjects [51–53]. Concurrently, extant studies employing optical neuroimaging techniques have demonstrated the capacity to assess various forms of cerebral activity, including physical activity [54,55], visual activation [56,57], and cognitive task performance [51,57,58]. This ability is predicated on the premise that heightened cortical brain activity is concomitant with elevated levels of oxygenated hemoglobin and diminished levels of deoxygenated hemoglobin, phenomena that manifest within seconds of the onset of augmented brain activity [59].

Based on these mechanisms, in neuroimaging, studies have reported a significant effect of regular exercise on cognitive function in older adults with and without MCI [15,16]. Some studies have indicated

that sexercise interventions enhance the amount of gray and white matter in the prefrontal cortex, restingstate functional connectivity between the medial prefrontal cortex and medial temporal lobe, and the function of the dorsolateral prefrontal, occipital parietal, and anterior cingulate cortex in the executive control network [60,61]. It has also been reported that the mind-body exercise intervention, Baduanjin, increases resting functional connectivity between the bilateral hippocampus and prefrontal cortex and may delay memory decline due to aging [62]. In summary, exercise has a positive and significant effects on brain structure [19,63] and brain function [64].

5 Limitations and Implications

The current study provides significant findings regarding effects of exercise on cognitive function. Nevertheless, this study has some limitations. The main outcome measures employed in the current study were MoCA and MMSE. A meta-analysis of the extant literature revealed significant heterogeneity among the findings. This result is hypothesized to have occurred because the environment, methods, and duration of physical activity interventions varied from study to study. Furthermore, the observed publication bias in combining the two measurement techniques is believed to result from differences in the susceptibility and specificity of the cognitive function assessment instruments, along with variations in evaluation criteria, even though the total scores on MoCA and MMSE assessments are equivalent.

MoCA is sensitive to MCI and early dementia; however, it carries a high risk of false positives among normal subjects. It evaluates various cognitive domains, including executive function, but its results are significantly influenced by education level and language proficiency. In comparison, MMSE demonstrates lower sensitivity than MoCA in detecting MCI but exhibits higher specificity in distinguishing normal from abnormal subjects. Nevertheless, its assessment of cognitive domains remains limited and is influenced by educational and linguistic factors. Therefore, selecting the appropriate instrument for a specific assessment or adopting a complementary approach is crucial to maximize each tool's strengths while addressing their respective limitations.

The number of articles applied to the meta-analysis may not be sufficient. However, the number of studies applied for a meta-analysis is not depend on the researcher's control, and it is technically feasible to performe a meta-analysis with more than two studies [65]. In addition, applying a general framework for MCI raises the problem that other potentially pathogenic processes and subtypes may be confounded in the MCI diagnosis. The training period was relatively short, and some training was not sufficiently intense to optimize neurophysiological or neuropsychological changes.

Future research should employ more effective measures and tests of cognitive function to assess longitudinal changes, in addition to the MoCA and MMSE. The most critical issue in this field is to expand findings to evaluate the impact of cognitive improvement on daily activities, quality of life, and psychological well-being. Furthermore, research is needed that considers various factors, such as frequency, intensity, time, and type of exercise, which may positively influence both activities of daily living and cognitive function in people with MCI. In spite of these limitations, the current study offers significant data on the effects of physical activity strategies on the cognitive function of individuals with MCI.

6 Conclusions

The current study carried out a meta-analysis to determine the effects of physical activity on cognitive function in people with MCI. The conclusions are as follows. Physical activity has significant effects on cognitive function in people with MCI. Based on these findings, it is concluded that the current study provides fundamental knowledge for developing physical activity interventions to improve cognitive function in MCI. Acknowledgement: We acknowledge all participants involved in this research and those who helped in recruiting.

Funding Statement: The authors received no specific funding for this study.

Author Contributions: Jonghwa Lee and Dojin An designed the study. Youngho Kim and Jonghwa Lee collected data. All authors reviewed the results and approved the final version of the manuscript.

Availability of Data and Materials: The raw data supporting the conclusions of this article will be made available by the author, without undue reservation.

Ethics Approval: Not applicable.

Conflicts of Interest: The authors declare no conflicts of interest to report regarding the present study.
